How Important are the International Financial Market
Imperfections for the Foreign Exchange Rate Dynamics: A Study of
the Sterling Exchange Rate

Xue Dong∗ Patrick Minford† David Meenagh‡

April 30, 2018

Abstract

The UK has been a net debtor over the past two decades and the sterling exchange rates are sensitive
to any chaos that might occur in the financial market. This paper examines the importance of the inter-
national financial imperfections in the sterling exchange rate dynamics. We build a small open economy
DSGE model with the constrained international financial institutions that intermediate capital flows,
and derive tractable analytical solutions. The constraint works to introduce a wedge between lending
and borrowing rates, which compensates financiers for their currency risk-taking. The model has been
estimated by using a simulation-based Indirect Inference approach, which provides a natural framework
for testing the hypothesis implied by the model. We find that the model cannot be rejected by the UK
data. Shocks to financial forces are the main driving forces behind the large and sudden depreciation
of the Sterling exchange rates in the aftermath of the collapse of Lehman Brothers and the Brexit vote.
Furthermore, the optimal policy rules have been proposed.

1 Introduction

The global financial crisis of 2008-2010 has challenged our conventional understanding of the international financial system and international capital flows, with its assumptions that financial markets are frictionless and exchange rate fluctuations are driven by fundamentals. Instead it now seems more promising to assume that international financial markets are imperfect and financial intermediaries require compensation for absorbing any imbalance between demand and supply of assets denominated in different currencies. This world harks back to that of the portfolio balance approach (Kouri, 1976) of the exchange rate determination on the imperfect capital substitutability.

Recently the UK has been persistently running a large current account deficit, which needs financing from abroad. Large-scale capital flows mostly are intermediated by international financial institutions. As a net debtor country’s currency, the sterling exchange rates are sensitive to any chaos that might occur in the financial markets: there was a massive sterling depreciation at the end of 2007; Britain’s surprise decision to leave the European Union was followed by financial market tumult. Sterling dropped below $1.32, a 31 year low. Such plunges in Sterling during financial disruptions cannot be fully explained by macroeconomic fundamentals.

The central issue, in our view, is how important are the financial market imperfections in the sterling exchange rate dynamics. We construct a small open economy dynamic stochastic general equilibrium (DSGE) model with international financial imperfections. Following the model developed by Gabaix and Maggiori (2016), we assume that international financiers are constrained to intermediate capital flows across countries in Section 2. The constraint works to introduce a wedge between lending and borrowing rates, which compensates financiers for their currency risk-taking. The model’s implied causal relationship between the financial market imperfections and exchange rate dynamics is formally tested for its closeness to the UK experience through the method of Indirect Inference developed by Minford et al. (2009). We find that the model is accepted by the historical UK data.

Based on this framework, we examine the driving forces of sterling exchange rate dynamics in financial disruptions. Furthermore, we answer the question how much do the constrained international intermediation of capital flows to the fiscal policy and macroprudential policy matter.

The paper contributes to the literature in three aspects. First, it provides new insight on the exchange rate determination in the context of financial forces, especially the impacts of shocks to financial forces on sterling exchange rate dynamics. One innovation of the paper is to extend the small open economy DSGE model to include Gabaix-Maggiori (2016) features in the international financial sector.

Second, the paper contributes to a growing literature on resolving the exchange rate disconnect puzzle and
the uncovered interest rate parity puzzle (Obstfeld and Rogoff, 2000). This paper shows that the exchange rate is disconnected from traditional macroeconomic fundamentals and international financial intermediaries could be the source of financial shocks that distort exchange rates. Moreover, the paper studies how financial forces affect currency risk premium, and accounts for the failure of the uncovered interest parity.

The paper also connects with the literature on financial frictions in an international context. A key insight is that financial frictions act as amplifiers of external shocks on the exchange rate and other key UK macroeconomic variables. To the best of our knowledge, we are the first in the literature to test whether financial frictions have impacts on exchange rate dynamics, and to estimate the international financial risk bearing capacities using UK data. The Indirect Inference estimation and testing technique is powerful enough to give policymakers a set of policy rules.

The paper is organized as follows. Section 2 describes the model. Section 3 outlines the Indirect Inference methodology. All aspects of the baseline model are tested when testing for the financial imperfection. We also estimate the global financier’s average risk-bearing capacity using Indirect Inference in Section 4. Section 5 empirically analyses sterling exchange rate dynamics during the financial disruptions. Policy implications are the subject of Section 6. Section 7 concludes. Some peripheral technical derivations and data descriptions are delayed to Appendix.

2 The Model

The core framework is the Real Business Cycle model of a small open economy without the assumption of nominal rigidities developed by Uribe and Schmitt-Grohe (2016). To this, we add risk-averse international financial intermediaries that facilitate international assets transactions between the home country and the rest of the world. An agency problem constrains the ability of global financial intermediaries to absorb imbalances between the demand and supply of bonds denominated in different currencies arising from international trades. Thus, they require a currency risk premium proportional to the size of their currency exposures.

Consider an infinite periods world economy. Time is discrete and indexed by \( t \in \{0, \infty\} \). The world economy is inhabited by a small open domestic economy and by the rest of the world. Goods are tradable among all countries, and there is a single industry and one broad type of consumption good traded at the global level. Both the domestic economy and the rest of the world can issue a risk-free one-period bond. The international financial market is imperfect due to international financial intermediaries’ limited risk-bearing capacities. Hence, uncovered interest parity does not hold in the model.

\[^{1}\text{Meenagh et al.} (2009)\] argued that the degree of nominal rigidities varies with changes in monetary regime. To avoid the issue of structure breaks, I choose a flexible price model rather than the model with nominal rigidities as an appropriate backdrop and focus on the real term behaviours of the economy.
The basic ingredients of the model are characterised in the following.

2.1 Representative Household Problem

The domestic economy is populated by an infinite number of identical households with preferences described by the utility function,

\[ E_0 \sum_{t=0}^{\infty} \beta^t U(C_t, N_t) \]  

where \( C_t \) denotes consumption, \( \beta \in (0, 1) \) is the subjective discount factor, the symbol \( E_0 \) denotes the expectation operator conditional on the information available at period 0. \( U(\cdot) \) is a period constant relative risk aversion (CRRA) utility function which takes the following additively separable form,

\[ U(C_t, N_t) = \omega_0 \varepsilon_t^{C_t} \frac{C_t^{1-\gamma_C}}{1-\gamma_C} - (1 - \omega_0) \varepsilon_t^N \frac{N_t^{1+\gamma_N}}{1+\gamma_N} \]  

Households enjoy utility from goods consumption, \( C_t \), while they receive dis-utility from labour supply, \( N_t \). \( \gamma_C > 0 \) is the Arrow-Pratt coefficient of relative risk aversion for consumption, and its reciprocal, \( \frac{1}{\gamma_C} \), measures the inter-temporal substitution elasticity between consumption in two consecutive periods. \( \gamma_N \), which is greater than 0, is the inverse of Frisch labour supply elasticity. \( \omega_0 (0 < \omega_0 < 1) \) is a preference weight of consumption in the utility function. \( \varepsilon_t^C \) and \( \varepsilon_t^N \) are preference shocks, which affect the inter-temporal and the intra-temporal decision of households, respectively. Both shocks are assumed to follow a first-order autoregressive process with an i.i.d. error term.

We assume that each period the representative household supplies \( N_t \) hours to the labour market and earns consumer real wage \( (w_t) \), which is equal to the producer wage deflated by the consumer price index. Households finance their expenditure through labour income \( (w_t N_t) \), total profit income \( (\Pi_t) \) received from the ownership of shares of domestic firms, and financial instruments in the form of risk-free bonds issued by the domestic government and the rest of the world. Domestic households are able to borrow credit, \( D_{t+1} \), from the home government at the rate of interest \( r_t \). However, home households are not able to borrow directly from foreign countries. Instead they borrow credit, \( D_{t+1} \), from the international intermediary who is willing to supply credit at the rate of interest, \( \tilde{r}_t \). To emphasise the currency mismatch that the international financial intermediary has to absorb, we assume that the home country only trades in its own currency bonds\(^2\). A risk-free bond issued by the rest of the world is intermediated by a representative international financier.

Both financial instruments, \( D_{t+1}, \tilde{D}_{t+1} \), with time subscripts \( t+1 \) are the households’ debt positions

\(^2\) \( \tilde{D}_{t+1} \) is denominated on home currency

\(^3\)Risk-free here refers to paying one unit of foreign general consumption basket in all states of the world.
with a unit price at \( t \), and require one plus the rate of interest agreed at time \( t \) in the following due period \((t + 1)\). They use those funds to purchase consumption goods, \( C_t \), and pay back the principal and interest on its outstanding domestic and foreign debts, \((1 + r_{t-1})\) and \((1 + \tilde{r}_{t-1})\), respectively. Also, households are taxed by a lump-sum transfer, \( T_t \); marginal tax rates are not included in the model explicitly and appear implicitly in the error term of the labour supply equation.

The period-by-period budget constraint of the representative household is given by

\[
C_t + D_t(1 + r_{t-1}) + \tilde{D}_t(1 + \tilde{r}_{t-1}) + T_t = w_tN_t + \Pi_t + D_{t+1} + \tilde{D}_{t+1}. \tag{3}
\]

The household chooses processes \( \{C_t, N_t, D_{t+1}, \tilde{D}_{t+1}, \lambda_t\}_{t=0}^{\infty} \) to maximise his utility (Equation (1) and Equation (2)) subject to his budget constraint (3) and no-Ponzi constraints of the forms,

\[
\lim_{j \to \infty} E_t \frac{D_{t+1+j}}{\prod_{j=0}^{\infty} (1 + r_j) \leq 0} \tag{4}
\]

\[
\lim_{j \to \infty} E_t \frac{\tilde{D}_{t+1+j}}{\prod_{j=0}^{\infty} (1 + \tilde{r}_j) \leq 0}, \tag{5}
\]

taking the processes \( \{r_t, w_t, \tilde{r}_t, \Pi_t, T_t\}_{t=0}^{\infty} \) and the initial conditions \( D_0(1 + r_{-1}) \) and \( \tilde{D}_0(1 + \tilde{r}_{-1}) \) as given. The conditions in Equation (4) and Equation (5) imply that debts do not grow faster than their corresponding interest rates.

The household’s first order condition for inter-temporal substitution in consumption is

\[
\frac{U_C(C_t, N_t)}{1 + r_t} = \beta E_t U_C(C_{t+1}, N_{t+1}). \tag{6}
\]

The intra-temporal condition is,

\[
- \frac{U_N(C_t, N_t)}{U_C(C_t, N_t)} = w_t. \tag{7}
\]

And a no-arbitrage condition is,

\[
r_t = \tilde{r}_t. \tag{8}
\]

Equation (8) equates the real rate of return on the bonds issued by the domestic government to the real rate of interest on the bond supplied by the international financier. Hence the domestic households have no preference on either of the financing methods, and we can refer to a single asset return, \( r_t \).

This small open economy model assumes that the domestic country has a single, perfectly competitive final goods sector, producing a version of the final good that is distinct from the product of the foreign
country. It is a single-industry version of the Armington model (Armington, 1969; see also Feenstra et al., 2014). Armington assumes that home and foreign goods are differentiated purely due to their origin of production. Households in the home country consume a domestically traded good, and an imported good. The home consumption index includes only one type of good, $C_t$, which is divided between home tradable, $C^d_t$, and foreign tradable consumption goods, $C^f_t$. Differentiated products of a given type bring utility to the household via a constant elasticity of substitution (CES) aggregator utility function,

$$C_t = \left[ \omega \left( C^d_t \right)^{\theta} + (1 - \omega) \left( \varepsilon^M_t \right)^{\theta} \left( C^f_t \right)^{\theta} \right]^\frac{1}{\theta}$$

where $\omega$ is the weight of domestically produced tradable goods, and $\theta > 0$ is the elasticity of substitution between home and foreign tradable goods. $\varepsilon^M_t$ is a random preference shock of home demand for foreign produced goods.

The level of consumption $\tilde{C}_t$ chosen above must satisfy the expenditure constraint on consumption,

$$\tilde{C}_t = p^d_t C^d_t + Q_t C^f_t$$

where $p^d_t$ denotes the domestic goods price level, $P^d_t$, relative to the general price level, $P_t$. $Q_t$ is the relative price of home and foreign countries’ consumption basket. It is a unit free measure of the price of the foreign consumption goods $P^F_t$ relative to the general price level in home country $P_t$ defined as $Q_t = \frac{S_t P^F_t}{P_t}$, where $S_t$ is the nominal exchange rate and is given in terms of domestic currency needed to buy a unit of foreign currency. Intuitively, an increase in $Q_t$ can be thought of as a real exchange rate depreciation, as it implies a real depreciation of domestic goods on the world market and a rise in the competitiveness of domestic exports. I treat the consumption bundle as the numeraire and, consequently, its price equals 1 in the domestic currency. Given that, all prices in the budget constraint are expressed relative to the general price level, $P_t$. Hence, in terms of the domestic currency, the unit cost of imported goods, $C^f_t$, is $Q_t$.

The domestic household chooses processes $\{C^d_t, C^f_t\}_{t=0}^\infty$ to maximise composite utility index (9) subject to the constraint that

$$C_t \leq \tilde{C}_t,$$

taking as given the relative prices $\{p^d_t, Q_t\}_{t=0}^\infty$.

---

4The value of $\omega$ is crucial since it describes the degree of home bias in preferences. $\omega > \frac{1}{2}$ implies a bias towards domestic produced tradable goods relative to imported goods from the rest of the world. Domestic produced goods and imported goods are perfect substitutes if $\theta$ approaches infinity; those goods are perfect complements if $\theta$ approaches zero. The degree of substitution between home-produced and imported goods may be affected by economic reasons, such as product quality or industry features, and also influenced by political variables and strategies.

5At the point of the maximum the constraint is binding, so that the consumption-equivalent utility, $C_t$ (the variable that appears in Equation (9)), is equal to the amount spent on consumption goods, $C_t$ that the variables appears in household’s budget constraint.
Hence, the domestic demand for foreign produced goods (import equation) is given by the optimality condition,

\[ C^I_t = IM_t = (1 - \omega)\varepsilon^M_t (Q_t)^{-\theta} C_t \]  

(12)

The domestic demand for home goods is positively affected by total consumption in the home country, \( C_t \), and negatively by the price of domestic produced goods relative to the general price level, \( p^d_t \); while domestic import depends positively on the total home consumption of goods, \( C_t \), and negatively on the real exchange rate, \( Q_t \).

### 2.2 Relationship with the Rest of the World

Given Equation (12) above, there exists a symmetric equation for the rest of the world which describes the foreign demand for domestic goods. Hence, this export equation for the home economy is

\[ EX_t = (1 - \omega^F)\varepsilon^X_t (Q_t)^{\theta^F} C^F_t \]  

(13)

where \( EX_t \) denotes the foreign demand for domestic goods (export from domestic country to the rest of the world). \( \omega^F, C^F_t \) and \( \theta^F \) are the foreign equivalents to home bias, total consumption of goods and the elasticity of marginal substitution between domestic and imported goods, respectively. \( \varepsilon^X_t \) is the random preference shock to the foreign demand for domestic goods. The volume of export demand goes up when total consumption of goods in the rest of the world, \( C^F_t \), increases. A depreciation of real exchange rate (a rise in \( Q \)) induces a rise in the competitiveness of domestic exports. Total consumption of goods in the rest of the world, \( C^F_t \), is treated as an exogenous variable given by a first-order autoregressive process,

\[ \ln C^F_t = \rho^C \ln C^F_{t-1} + \eta^C, t \]  

(14)

where \( \eta^C, t \) is an independent and identically distributed innovation.

### 2.3 Representative Firm Problem

The output of the economy is assumed to depend on a production function that combines labour and capital inputs. Firms operate in perfectly competitive product and factor markets. A representative firm hires labour, purchases new capital goods to produce an homogeneous final good using production technology given by

\[ Y_t = A_t N_t^\alpha K_t^{1-\alpha} \]  

(15)
where $A_t$ is a random productivity shock variable and reflects the state of technology. $Y_t$ is an output of the economy. $\alpha$ ($0 \leq \alpha \leq 1$) is the output elasticity of labour.

Capital evolves according to the following law of motion

$$K_{t+1} = (1 - \delta)K_t + I_t$$

(16)

where $K_t$ is predetermined capital stock, $I_t$ is the firm’s investment, and $\delta$ measures the depreciation rate.

Assuming free entry into the industry and a large number of firms operating under perfect competition. The firm maximises the present discounted value of profits,

$$\pi_0 = E_0 \sum_{t=0}^{\infty} \beta^t \frac{\bar{\lambda}_t}{\lambda_0}[Y_t - (\tilde{w}_t + \varepsilon_t^{N^d})N_t - I_t - \frac{\kappa}{2}(K_{t+1} - K_t)^2]$$

(17)

subject to the constant-return-to-scale production technology and quadratic adjustment costs for capital, through its choices of $\{N_t, I_t\}_{t=0}^{\infty}$, taking prices $\{\tilde{w}_t, \bar{\lambda}_t\}_{t=0}^{\infty}$ and initial condition $K_0$ as given. $\kappa$ denotes a multiplicative constant affecting adjustment costs. $\varepsilon_t^{N^d}$ is the shock to the net rental cost of labour.

The first order conditions give the firm’s demand for labour condition,

$$N_t = \alpha \frac{Y_t}{\tilde{w}_t + \varepsilon_t^{N^d}};$$

(18)

and a non-linear difference equation in capital,

$$K_{t+1} = - \frac{1}{\kappa} + K_t + \frac{1 - \alpha}{\kappa(1 + r_t)} \frac{E_t Y_{t+1}}{K_{t+1}} + \frac{1 - \delta}{\kappa(1 + r_t)} - \frac{E_t K_t + \kappa}{1 + r_t} - \frac{\varepsilon^K_t}{\kappa}. \quad (19)$$

Equation (19) could be named as the demand for capital, and its non-linearity is caused by the quadratic capital adjustment costs that the firm faces. $\varepsilon^K_t$ represents the shock to the net rental cost of capital.

### 2.4 International Financial Intermediary

We follow the spirit of Gabaix and Maggiori (2016) to develop an open economy model with financial frictions in the intermediation process of international capital flows. Domestic households can freely trade domestic assets, i.e. $D_{t+1}$, however, they are constrained in their holdings of foreign assets. There is a unit mass of

$\tilde{w}_t = \frac{w_t}{p_t} = \frac{w_t}{\left[1 - (1 - \omega)\epsilon_t^Q(1 - \theta)\frac{1}{\omega}\right]}$. 

The real rental price of labour paid by the domestic firm, $\tilde{w}_t$, is the nominal wage relative to the unit value of domestically produced goods. It is different from the real wage referred to the household problem, $w_t$. 

$$\tilde{w}_t = \frac{w_t}{p_t} = \frac{w_t}{\left[1 - (1 - \omega)\epsilon_t^Q(1 - \theta)\frac{1}{\omega}\right]}.$$
global financial firms in the global financial market, who can actively invest in bonds denominated in both of home currency and foreign currencies and are hence able to absorb any excess supply and demand of assets. Furthermore, financiers with no capital of their own face limited commitment constraints.

For simplicity, we assume that the financiers are owned by households from the rest of the world and the management of financial firms is a one-period job. At the end of each period, financiers pay their profits and losses out to the owners. The representative financier’s balance sheet consists of \( \tilde{D}_{t+1} \) domestic currency, and \(-\frac{\tilde{D}_{t+1}}{Q_t}\) foreign currency, where \( \tilde{D}_{t+1} \) is the value in domestic currency\(^7\) of domestic currency-denominated bonds the financier is long of, and \(-\frac{\tilde{D}_{t+1}}{Q_t}\) the corresponding value in foreign currency of foreign currency-denominated bonds. The subscript \( t + 1 \) expresses the maturity date of those financial instruments, which are issued at time \( t \).

Suppose that the expected value of his financial firms is generated by lending \( \tilde{D}_{t+1} \) to domestic households at the interest rate \( \tilde{r}_t \) and capturing corresponding funds \( \frac{\tilde{D}_{t+1}}{Q_t} \), from the rest of the world at the world interest rate \( r^f_t \). It is given by

\[
V_t = E_t \left\{ \frac{\beta^{\tilde{N}_t+1}}{\tilde{\lambda}_t} \left[ (1 + \tilde{r}_t) - (1 + r^f_t) \frac{Q_{t+1}}{Q_t} \right] \tilde{D}_{t+1} \right\}.
\]

Note that values are discounted using the factor \( \frac{\beta^{\tilde{N}_t+1}}{\tilde{\lambda}_t} \), which is the value assigned by the financier to contingent payments of goods in period \( t + 1 \) in terms of units of goods in period \( t \). Since the financier pays back the principle to foreign countries one period later, the value of liability, \(-\frac{\tilde{D}_{t+1}}{Q_t}\) should be adjusted with the expected relative price at the maturity date \( t + 1 \), that is, expected real exchange rate, \( E_t Q_{t+1} \).

The financiers’ borrowing process is subject to an agency friction that imposes a restriction on the size of the balance sheet of the financiers, which prevents perfect arbitrage between domestic-currency denominated bonds and foreign-currency denominated bonds. To take the role of limited financial risk-bearing capacity by the financiers, we assume that financiers can divert a portion \( \varepsilon^f_t \Gamma \left| \frac{\tilde{D}_{t+1}}{Q_t} \right| \)\(^8\) of the funds they intermediate in each period. Rational foreign lenders anticipate the incentives of the financier to divert funds and are willing to lend as long as the following constraint \((21)\) holds

\[
\frac{V_t}{Q_t} \geq \left| \frac{\tilde{D}_{t+1}}{Q_t} \right| \varepsilon^f_t \Gamma \left| \frac{\tilde{D}_{t+1}}{Q_t} \right|.
\]

The left-hand side of Equation \((21)\) measures the intermediary value in foreign currency, while the right-hand side is the total divertable funds, which is convex in \( \tilde{D}_{t+1} \). In addition, the value of the financier’s financial

---

\(^7\)In the absence of a nominal side to the model, the currency means a claim to the numeraire of the economy; domestic currency-denominated or foreign currency-denominated mean values expressed in units of general consumption baskets in each economy.

\(^8\)In order to make economic sense the constraint must satisfy that \( \varepsilon^f_t \Gamma \left| \frac{\tilde{D}_{t+1}}{Q_t} \right| \leq 1 \). That is, the global intermediary cannot steal more than 100 percent of the funds borrowed.
firm is linear in the position \( \tilde{D}_{t+1} \), hence the constraint, Equation (21), always binds. The constraint limits the maximum position the financiers can take. The parameter \( \Gamma \) (\( \Gamma \geq 0 \)) captures the ability of financiers to bear risks, and governs the debt elasticity of the country interest rate. \( \varepsilon^\Gamma_t \) is the financial shock which alters the financiers’ risk bearing capacity.

The representative financier chooses processes \( \{ \tilde{D}_{t+1} \}_{t=0}^\infty \) to maximise the expected value of his financial firms, Equation (20) subject to his limited commitment constraint (21), taking as given the processes \( \{ \tilde{r}_t, r^f_t, Q_t, \tilde{\lambda}_t \}_{t=0}^\infty \). We obtain

\[
\tilde{D}_{t+1} = \frac{1}{\varepsilon^\Gamma_t \Gamma} \left[ Q_t - \frac{(1 + r^f_t)}{(1 + r_t)} E_t Q_{t+1} \right].
\] (22)

Equation (22) shows the financiers’ downward sloping demand for domestic currency. Alternatively, it shows the supply of foreign credit converted in home currency intermediated by the global financier.

The parameter \( \Gamma \) governs the size of the balance sheet of the global financial intermediaries and is hence an inverse measure of their risk-bearing capacity. Intuitively, an increase in the value of \( \Gamma \) leads to a decrease in the financiers’ ability to carry the currency risk of their portfolio; in addition, their domestic asset demand curve becomes steeper due to the rise in the required compensation per unit of risk, and the global asset market tends to be more segmented. In particular, as the value of \( \Gamma \) goes to infinity, then the demand for domestic bonds, \( \tilde{D}_{t+1} \) goes to 0. In this case, the financiers are unable to take any position, put differently, they are unwilling to absorb any imbalance, for example, those caused by the trade flows. On the other hand, as the value of \( \Gamma \) goes to 0, then the financier is willing to trade (either borrow or lend) as much as possible in domestic currency-denominated and foreign currency-denominated bonds given any non-zero expected excess return in the global financial market. In this situation, uncovered interest parity holds, that is, assets from different countries have the same expected rate of return when they are converted into the same currency.

Equation (22) implies the determination of real exchange rate, which is

\[
Q_t = \frac{1 + r^f_t}{1 + r_t} E_t Q_{t+1} + \varepsilon^\Gamma_t \Gamma \tilde{D}_{t+1}.
\] (23)

The behaviour of exchange rate and currency risk premium are linked to home country’s external imbalances in a setting in which assets are imperfect substitutes.

There are two distinct channels - interest rate differentials channel and currency risk-taking channel through net foreign debt (asset) positions which affect currency excess returns. By providing a simple and tractable specification for the credit constrained problem, we emphasise that the financier’s demand function captures the feature of limits of arbitrage theory and the spirit of international financial intermediation.
2.5 Government

The government’s sources of income are tax revenue collected from households, and the issuance of new
government bonds maturing one period ahead, \(-D_{t+1}\). Government’s spending consists of goods of con-
sumption, \(G_t\), which is assumed to be non-productive and made up strictly of welfare transfers, and interest
payments on government debt agreed at a previous period, \(-r_{t-1}D_t\). The sequential budget constraint of
the government is then given by

\[ T_t - D_{t+1} = G_t - D_t(1 + r_{t-1}) \]  (24)

where \(T_t\) is a lump-sum tax, capturing the revenue effects of all tax instruments that affect the household.
Government spending \(G_t\) is treated as an exogenous variable given by the first-order autoregressive process,

\[ \ln G_t = \rho_G \ln G_{t-1} + \eta_{G,t}. \]  (25)

2.6 Market Clearing Conditions

According to Walras’ Law in general equilibrium theory, demand should be equal to supply in each market.

This leads to the following market clearing conditions in goods market for home country,

\[ Y_t = C_t + I_t + G_t + EX_t - IM_t. \]  (26)

We consider the fundamental balance-of-payments identity in the open economy,

\[ \tilde{D}_{t+1} - \tilde{D}_t = r_{t-1} \tilde{D}_t + IM_t Q_t - EX_t. \]  (27)

It says that the change in the country’s net foreign debt position equals the repayment of foreign debt from
the previous period and the net import.

3 The method of Indirect Inference

Indirect Inference was first introduced into the econometrics literature by Smith (1993), and extended as a
general simulation-based method for estimation of structural models by Gourieroux et al. (1993). Moreover,
Indirect Inference can be used in a structural macroeconomics model evaluation, which was proposed in
Minford et al. (2009) and refined by Le et al. (2011) who used Monte Carlo experiments to evaluate the
power of the Indirect Inference test.
We use Indirect Inference rather than the recent widely-used Bayesian method to estimate our model here, since we aim to test the model against the data. The Bayesian method cannot judge models in the classical hypothesis testing sense, they treat all models as false and evaluate each model’s probability of being right instead. It is not precisely where the line is drawn between failure and success for the model. Moreover, a criticism of the Bayesian method is the choice of the priors that is subjective. Any model ranking or probability assessment we made under the Bayesian approach would be biased if priors are incorrect. As the first empirical study in the literature to estimate financiers’ risk bearing capacity (Γ) there is no prior information on this parameter and the Bayesian method is not applied here.

By contrast, Indirect Inference provides a classical statistical inferential framework for judging whether a model with a particular set of parameters could have generated the behaviour found in a set of actual data. The Indirect Inference test is to compare the performance of the auxiliary model based on the actual data with its performance based on the data simulated from the macroeconomic model. The auxiliary model\(^9\) is employed to form a criterion function in the indirect inference test. This criterion does not need to be an accurate description of the data generating process. Common choices of this criterion are the scores, impulse response function, or actual coefficients. Here we choose the auxiliary model parameter estimates (or functions of these) as the descriptors of the data. The structural model is then simulated\(^{10}\). We use a Wald statistic depending on the distance between \(\hat{\beta}^a\), the estimates of data descriptors based on actual data, and \(\beta^s(\hat{\theta}_0)\)\(^{11}\), the mean of their distribution based on multiple independent sets of the simulated data, which is given by

\[
WS = (\beta^a - \beta^s(\hat{\theta}_0))^\prime \Omega^{-1} (\beta^a - \beta^s(\hat{\theta}_0)),
\]

where \(\hat{\theta}_0\) is the vector of parameters of the DSGE model on the null hypothesis that it is true. \(\Omega = \text{cov}(\beta^i(\hat{\theta}_0) - \beta^s(\hat{\theta}_0)) = \frac{1}{s} \sum_{i=1}^s (\beta^i(\hat{\theta}_0) - \beta^s(\hat{\theta}_0))(\beta^i(\hat{\theta}_0) - \beta^s(\hat{\theta}_0))^\prime\) is the variance-covariance matrix of the distribution of simulated estimates \(\beta^i\). Thus, if the model proposed in Section 2 is correct, the estimates of data descriptors based on the actual data will lie in some confidence interval implied by their distribution derived from multiple independent sets of the simulated data. To estimate the structural model we use a Simulated Annealing algorithm in which the search takes a place over a wide range around the calibrated values to find the minimum-value Wald statistic for the model. This gives the best fit of parameters that

\(^9\)The auxiliary model is independent of the theoretical model and the performance of the theory is evaluated indirectly against it. It “serves as a window through which to view both the observed data and the simulated data generated by the economic model: it selects aspects of the data upon which to focus the analysis” (Durlauf and Blume, 2008).

\(^{10}\)The structural residuals of each equation are backed out from the observed data and the DSGE model. The resulting structural residuals are treated as the error process in the model and together with exogenous variable processes, process the shocks perturbing the model. Instead of assuming shocks follow asymptotic distributions, the shocks are bootstrapped by time vector to preserve any correlations between them.

\(^{11}\)\(\beta^s(\hat{\theta}_0) = E(\beta^i(\hat{\theta}_0)) = \frac{1}{s} \sum_{i=1}^s \beta^i(\hat{\theta}_0)\) denotes the sample average of estimates of the coefficients in auxiliary model based on \(s\) sets of simulated data from the macroeconomic model, taking \(\hat{\theta}_0\) as given.
produce the simulations that are statistically the closest to actual data.

In practice, the solution to a log-linearised DSGE model takes the form of a restricted vector autoregressive and moving average (VARMA), or approximately, a vector autoregressive (VAR). Following Le et al. (2016), we use a VECM as the auxiliary model for non-stationary data, which is then re-expressed as a cointegrated VAR with exogenous variables (VARX(1)) for our three main macroeconomic variables of interest (real interest rate, output and real exchange rate) including a time trend, and net foreign debt to GDP ratio and productivity residual as non-stationary exogenous variables. These exogenous terms have the impact of achieving cointegration.

We examine the structural model’s ability to encompass the dynamics, volatility and cointegrating relations observed in the data. To this end, we use the VARX(1) coefficients and the VARX(1) error variances as our descriptors of the data and then compute a Wald statistic from these.

4 Testing the model against the data

The data included in this study were obtained from the first quarter of 1975 to the last quarter of 2016 because the UK has had floating exchange rates among its major trading partners since the early 1970s. In order to capture the effects of the financial disruption on exchange rates, we include data during the turbulent periods from early 2008 until early 2013 due to the global financial crisis and the European debt crisis, and from early 2016 until late 2016 because of the Brexit vote. In general, the UK has very low capital controls, little probability of default and deep markets in foreign exchange. Therefore, these factors narrow the possible explanations for exchange rate puzzles.

There are some reasons why we use unfiltered data in this paper. First of all, the filters available do not seem appropriate and precise to decompose a non-stationary time series arbitrarily into a ‘long run potential trend’ component and swings around it since some transitional periods following a shock may be reasonably long in the model, and long cyclical swings might be mistakenly treated as a trend and removed by filters. Secondly, we would like to keep the features of non-stationarity and do not remove the stochastic trend. One of the important interests in this study is about how the stochastic trend behaviours, which arise from the unit root processes of technology shock, transfer through the entire model. Stationarising the data may potentially distort some of the interactions of interests and the dynamic properties of the model in ways that are not easy to uncover.

The majority of UK data are sourced from the UK Office of National Statistics (ONS). Others from Bank of England (BoE), Federal Reserve Bank of St. Louis, Bank for International Settlements (BIS), Gourieroux et al. (1993) show that a correct inference can be based on an ‘incorrectly’ specified auxiliary model. When the auxiliary model is correctly specified, the indirect inference is equivalent to maximum likelihood.

International Monetary Fund (IMF). A detailed description of the data used is given in the Appendix A.

The model is estimated by Indirect Inference method before its final test statistic is determined. Table 1 shows the estimation results for the structural model. All parameters are allowed to change some way from their calibration apart from quarterly discount factor ($\beta$), quarterly depreciation rate ($\delta$), and output elasticity of labour ($\alpha$) which are held fixed on theoretical grounds. On the international financial intermediary side, the global financiers’ average risk-bearing capacity within 1975Q1 to 2016Q4 is estimated at 0.3, which implies the global financial market is imperfect and uncovered interest parity does not hold. Financial intermediaries require premiums to absorb imbalances caused by the international trade.

With the set of estimated coefficients, the Direct Wald test presented in Table 2 suggests a strong non-rejection of the model with imperfect financial market at the 5% significant level, with a p-value in excess of 0.05. The Wald statistic based on observed data lies at around 68th percentile of the distribution of simulated estimates $\beta_s$.

In order to further test the hypothesis of imperfect financial market against the UK data, I vary the coefficient $\Gamma$. Holding other estimated coefficients unchanged, either lowering or increasing the value of $\Gamma$ would worsen the p-value. The lower and upper bounds of financiers’ risk bearing capacities have been found, which are $\Gamma_L = 0.05$ and $\Gamma_U = 0.95$, respectively. Thus, international financial imperfections indeed

have effects on the UK economy\textsuperscript{13}.

4.1 How reliable is the estimated model?

As the model users such as the policymaker, they might want to know how much they can trust this estimated model. To assess the chances of the test rejecting general parameter error we do a Monte Carlo experiment. We generate 10,000 samples from this model as the True model and then perturb all the parameters alternately by $+\text{ or } -x\%$ where we call x the ‘degree of falseness’. We can carry out our test on each False model and check how many of the 10,000 samples would reject it.

The Monte Carlo results are shown in Table 3 where it can be seen that once the model is 10\% or more False rejection reaches 100\%. This implies we can be sure, since the model we have has not been rejected, that it must be within a bound of True to 10\% False.

5 Model Analysis

5.1 Impulse Response Analysis

We start with two experiments designed to illustrate how the effects of shocks are magnified and distinct by the financial market imperfections, and how shocks arising in the financial sector itself influence the economy through currency risk-taking channel.

\textsuperscript{13}Many analyses, such as Meenagh et al. (2010), have been made with an Real Business Cycle open economy model of UK under uncovered interest parity and they have all passed the tests used in this paper. However, what this paper does is to investigate the case where there is a financial friction. Given UK experience the idea of a financial friction in foreign lending appears plausible.

The full UIP model and the financial friction model are non-nested: they are alternative ways of modelling foreign relationships. It is quite possible both can match the data. This might suggest that there is some more general model that nests them both; for example, it might be that sometimes there is UIP and sometimes there is friction. However, we do not investigate this here.
Figure 1 and Figure 2 show the response of the model economy to two disturbances: an external demand shock and a risk premium shock respectively. In each figure the red solid line shows the response of the estimated baseline model. The black dotted line gives the response of the model with nearly frictionless financial market ($\Gamma \approx 0$).\footnote{The model with $\Gamma = 0$ would introduce serious computational difficulties because the long-run levels of endogenous variables will depend on the behaviour of the non-stationary driving variables and “all available techniques are valid locally around a given stationary path” (Uribe and Schmitt-Grohe, 2003, p.164). Here, I set $\Gamma = 0.0001$ rather than $\Gamma = 0$ for computational simplicity.}

A 10% temporary drop in foreign demand results in an excess supply of the domestic goods, which generates a current account deficit and a rise in net foreign debt. On the one hand, the global financial intermediary currency risk-taking mechanism produces a modest amplification of the depreciation in the real exchange rate in the estimated baseline model relative to the model with nearly perfectly functioning financial market ($\Gamma \approx 0$). The amplification is mainly the product of the rise in exchange rate risk premium due to global financiers’ limited risk-bearing capacities. In the model without friction, of course, the premium is fixed at zero.
Figure 2: IRFs for a 1% global risk aversion shock to the estimated baseline model
On the other hand, the financiers’ limited commitment constraint leads to the opposite responses of domestic consumption and capital demand to external demand shock in the estimated baseline model, in contrast to those in the model with nearly perfectly functioning financial market. When the constraint binds, domestic households are not able to smooth out the impacts of the temporary export shock by running up foreign debts. This means, on effect, the domestic interest rate has to shoot up to drive down the domestic consumption. The increase in the cost of the capital reduces capital demand.

Global financial intermediaries act as shock absorbers; however, they are themselves the source of financial shocks that disturb the real economy. Here, we call them “global risk aversion shock”. An unanticipated 1% global risk averse shock reduces financiers’ risk bearing capacities. To incentivise global financiers to intermediate capital flows, the real exchange rate has to depreciate immediately and be expected to appreciate in the future through currency risk-taking channel. A tighter liquidity in international financial market push up the domestic interest rate, which induces a fall in domestic demand, including consumption, import and capital demand. In turn, output contracts. The labour market is also affected by the financial shock: real wage and hours worked decline initially as the shock hits the economy.

5.2 A Stochastic Variance Decomposition of the Financial Disruption Episode

Based on the estimated baseline model, we investigate what are the main driving forces of the sterling exchange rate during the episodes of financial disruptions by using a forecast error variance decomposition (or just variance decomposition for short) of the episode over 2006Q4 to 2016Q4, covering the global financial crisis and the Brexit vote.

Table 4 gives the variance decomposition of the sterling exchange rate, output, real interest rate and consumption. Shocks to financial forces account for more than 72% of the error variance of the sterling exchange rate during the period of financial disruptions. Furthermore, the bulk of the remainder comes from supply shocks, such as the productivity shock, the wage cost shock and the labour supply shock, which together contribute to 17 percent of the variation. The results of the variance decomposition of the exchange rate emphasises the crucial role of the currency risk-taking channel in explaining the variation of the sterling exchange rate in the imperfect financial market.

Shocks to financial forces explain more than a quarter of the variations in consumption, since costs of borrowing from the rest of the world to maintain the standard of consumption surge when there is a financial disruption. In addition, movements in consumption are primarily driven by supply shocks that affect the intra-temporal equations and another two shocks that influence the intertemporal Euler equations, i.e. the consumer preference shock which has impacts on both the consumption and investment and the

Note:  a). The values in the table are in the percentage level.  b). Shocks to Financial Forces include the export demand shock, the import demand shock and the global risk aversion shock.  c). Supply shocks include the productivity shock, the wage cost shock, and the labour supply shock.  d). Other demand shocks include the consumer preference shock, the factor demand shock, the government demand shock, the foreign consumption shock and the foreign consumer preference shock.

factor demand shock which affects the investment, in turn, the consumption.

Table 4 also illustrates that shocks to financial forces explain a minor fraction of the total variations in both the level of output and the interest rate, approximately 4%, whereas supply shocks, especially the productivity shock, play significant parts in generating the movements of them.

Therefore there is a distinct role for shocks to financial forces in such episodes of the financial disruption, and those shocks have important effects on the economy in this model, particularly the variation of sterling exchange rates.

5.3 Historical Decomposition of the Financial Disruption Episode

We then analyse what the estimated model says should happen in the economy over the same period of 2006Q4 to 2016Q4. In particular, we use the charts that follow for two main macro variables: sterling real exchange rate and output.

As can be seen in top panel of Figure 3, the pound experienced a sharp depreciation as the global recession loomed at the end of 2008, and shocks to financial forces made a major contribution to the surge in the sterling exchange rate. Shocks to interest rates also contributed to the pound depreciation, but with a small portion, because a deep recession triggered the Bank of England to slash interest rates, making the UK a far less attractive place for investors from abroad. On the other hand, a negative productivity shock put a limited pressure in appreciation.

Sterling depreciated to record level against top trading partners after the Brexit referendum vote at the third quarter of 2016. The departure from the European Union imposed an uncertainty on the UK’s future trade policy, fuelling fear and a lack of confidence. Not surprisingly, shocks to financial forces played a dominant role in the pound depreciation. The foreign demand of Sterling dropped due to the uncertainty of the UK’s economy after the Brexit vote. Notice that the red dash line in Figure 3 describes the path for Sterling behaviour for the currency premium model in which all the structural shocks are considered, and
Figure 3: Shocks decomposition of sterling exchange rate and output
the solid black line outlines the path for the model where the global risk aversion shock is excluded. By comparing those two paths for Sterling, we can find that the shock to the willingness of financiers to absorb exchange rate risk can produce the exchange rate disconnect properties and enlarge the volatility of sterling during a financial disruption.

The bottom panel of Figure 3 shows how the estimated currency premium model suggests the shocks drove output of the UK in the episode of financial disruptions. Britain entered a recession in the third quarter of 2008. In particular, productivity shocks play a largely dampening role on output, and shocks to financial forces are by far the most crucial component of the negative shocks to the output. After the collapse of Lehman Brothers, the Bank of England and other major central banks in the world stepped in the financial market. The base interest rates were globally cut to historically low levels, aiming to stimulate the economy. Shocks to interest rates made a positive contribution to the output over 2009 to 2011.

Although shocks to financial forces and the interest rate differential channels imposed downward pressure on output, Britain’s economy continued growing in the three months after the EU referendum because of the strong fundamentals of the UK economy.

6 Implications of the model for optimal policy rules

As a policymaker, you might want to know what would happen when a financial confidence shock and fiscal policy (we interpret it here as a government spending shock) hit the economy. Three key macroeconomic variables - output, real interest rate and real exchange rate have been chosen to analyse.

The upper panel of Figure 4 shows the effects of a decline in financial confidence in both the models with financial imperfections and perfections. In the model with financial imperfections, the effect is to tighten credit conditions in the global financial market and, in turn, push up the domestic real interest rate, which contracts the domestic aggregate demand. This drives down output immediately. Financiers require more compensation to facilitate capital flow, thus the real exchange rate depreciates and is expected to appreciate.

The lower panel of Figure 4 exhibits the impacts of a rise in government spending in both the estimated baseline model and the model with the perfect functioning international financial market. The government spending shock is more effective on output in the imperfect financial model than that in the perfect financial model. Thus, we argue that fiscal policy might hold the key to responding to crisis conditions.

We now focus on the estimated baseline model with financial imperfections and consider the welfare losses from responses to economic cycles through a macroprudential policy rule, a fiscal rule and a combination of those two rules, and compute the optimal degree of reaction. We take the variance of output and the
Figure 4: Responses to 1% financial confidence shock and government spending shock in the estimated baseline model and the model with the perfect functioning international financial market.
variances of consumption and labour supply as the objectives. For simplicity, we assume the distortions created by macroprudential policy would be offset by lump-sum transfer.

We consider a simple specification where the authority could set the interest rate on domestic bonds applicable to the international asset market in period $t$ according to the macroprudential policy rule

$$RP_t = \nu(\frac{\tilde{D}_t}{D_{t-1}} - 1)$$ (29)

where $RP_t$ is the regulation premium, which is defined as an increasing function of the net foreign debt growth in the economy. It implies that the growth of net foreign debts or capital flows has been chosen as the policy objective. $\nu$ is the adjusted coefficient.

In the presence of the macroprudential regulation, the international financiers’ demand for domestic bonds has been affected by the regulation premium. Thus, the lending cost for foreign borrowing becomes,

$$r_t = r^f_t + \ln Q_t + 1 - \ln Q_t + \Gamma \tilde{d}_t - RP_t.$$ (30)

When foreign borrowing grows, tightening of macroprudential policies would lower the interest rate on domestic bonds which makes domestic bonds less attractive to the global financiers. This, in turn, reduces the capital inflow during boom periods, driving down the demand for domestic currency (real exchange rate depreciation) and lowering trade deficits.

$$\ln G_t = \rho_G \ln G_{t-1} - \xi(\ln Y_t - \ln \bar{Y}) + \eta_{G,t}$$ (31)

The coefficients of policy rules $\{\nu, \xi\}$ have been derived optimally by computing the values that minimize the total welfare cost of economic agents under all the structural shocks. Table 5 presents a comparative analysis of alternative policies in terms of two groups of variances. The numbers presented in the Table are percentage changes in welfare costs in terms of the variance of consumption, labour supply and output relative to the baseline economy. A smaller percentage change implies a smaller welfare loss, and hence indicates that the policy is more desirable from a welfare point of view.

A thousand bootstrapped simulations have been run for each policy rule. Clearly, the three policy rules inject stabilising action when the economy collapses or surges. We observe that the welfare loss decreases by around 46 percent of variances of consumption and labour supply and by about 50% of the variance of output under a combination of macroprudential policy rule and fiscal policy rule. In terms of the consumer’s

---

15The macroprudential policy creates a wedge between the flexible price cost of capital and the prudential cost. Since the distortion is negligible and difficult to measure, we assume the cost of capital caused by the prudential policy could be offset by paying subsidy to firms.

utility, the reduction in welfare loss from using the macroprudential instrument is significant compared to the fiscal policy. In particular, the macroprudential rule plays a significant role in smoothing out consumption and decreases the volatility of consumption by 33 percent. However, the economy with the fiscal policy rule experiences much smaller fluctuation in output than the economy with the macroprudential instrument.

Moreover, we investigate economic stability implied by the model with each policy rule in terms of frequency of crisis. Here a ‘crisis’ is defined as a severe interruption in output growth for at least three years. We bootstrap the model with each policy rule and the full sample of implied shocks to see whether implementing policy rules could help to reduce the frequency of crisis. The result shows that the combination of fiscal and macroprudential rules offers a big rise in the stability by reducing the number of crises per 1000 years to 13.64 from the baseline 20.93. In other words, the frequency comes down to one episode every 73 years from the baseline 48 years under the combination of these two policy rules.

7 Concluding remarks

We developed a quantitative RBC open economy model of the UK where the global financial market is imperfect. We test all aspects of the baseline model when testing for the financial imperfections. A comfortable non-rejection of the hypothesis implied by the baseline model concludes that the international financial market imperfection channel indeed played a role in the sterling exchange rate dynamics and the UK economy over the period of 1975 and 2016. Moreover, the estimated financier’s average risk bearing capacity within the sample range is 0.3. Then, we find that shocks to financial forces are the main driving forces behind large and sudden depreciation of the Sterling exchange rates in the aftermath of the collapse of Lehman Brothers and the Brexit vote. Finally, macroprudential and fiscal policy rules have been proposed to improve the welfare and reduce the frequency of crisis.
References

Appendix A

We use data over the period 1975Q1-2016Q4 on eleven UK macroeconomic variables: output, consumption, capital stock, export, import, total hours worked, real wages, real interest rates, real exchange rates, net foreign debt to GDP ratio, government spending. Two variables for the rest of the world: world consumption and foreign real interest rates. We convert all real variables to a per capita basis by dividing by an working-age population index. All variables are expressed in constant prices and seasonally adjusted, unless specified otherwise. Most of variables are in natural logs, except where variables have already been expressed in percentages, such as net foreign debt to output and interest rates.

This Appendix includes all definitions, sources of data, symbol keys and the detail of transformations of some data series used in the paper.

Table 6: Data Description
Notes to Table 6

15. CVM represents chained volume measures.

16. Law of motion equation is $K_t = (1 - \delta) * K_{t-1} + I_t$. Here is the process of calculating capital stock,

   Step 1: start with the K/Y ratio (capital output ratio=2.69);

   Step 2: For a given year, I use initial output to calculate capital in first period $K_{1975Q1} = K_{1975Q1}$ (initial value);

   Step 3: Generating capital based on law of motion equation, $K_{1975Q2} = (1 - \delta) * K_{1975Q1} + I_{1975Q2}$.

17. Total employment (ONS code: MGRZ; units: thousands); Total actual weekly hours worked (ONS code: YBUS, units: millions); Take the number of MGRZ, normalized so that its 2010Q1 value is 1, called it total employment index (MGRZ index): $N = \frac{YBUS}{MGRZ} * MGRZindex$.

   Here is the website: http://www.bankofengland.co.uk/research/Pages/datasets/default.aspx.

19. Working population is the sum of total claimant count (ONS code: BCJD) and UK workforce jobs (ONS code: DYDC); take the number of working population, normalized so that its 2010Q1 value is 1, called it working population index.

20. Based on the bilateral trade with the UK, the sterling to euro, the sterling to dollar, and the sterling to Japanese yen bilateral exchange rates have been assigned majority of the weights in calculating sterling real effective exchange rate indices. Please find the detail in http://www.bis.org/statistics/eer.htm

21. According to the weights in sterling real effective exchange rate indices, the weighted average of nominal interest rate in Germany(0.62), US(0.23), Japan(0.15); Germany is a proxy for European Union.

22. FRED denotes Federal Reserve Bank of St. Louis; OECD stands for Organisation for Economic Co-operation and Development, data website https://data.oecd.org/

23. The weights assigned for countries in $P^F$ is the same as the weights in $R^f$.

24. One period ahead inflation (year-on-year change in $P^F$) based on the formula $\text{inflation rate} = \frac{CPI_t - CPI_{t-1}}{CPI_{t-1}}$.

25. Nominal net foreign debt is accumulated current account deficits (millions of pounds), taking the Balance of Payments international investment position as a starting point (ONS code: HBQC at 1974). I converted annual data series to quarterly by quadratic-match-sum.
